01 基本信息

- Title: Learning Interpretable Tumor Microenvironment Representations by Fitting Pan-Cancer Cell State–Niche Correlation
- Authors: Xiao Xiao*, Jiashu He, Shiyang Zhang, Meiyi Mao
- Source: arXiv preprint (2026-08-26), version v1
- URL: <http://arxiv.org/abs/2608.26208v1>
- PDF URL: <https://arxiv.org/pdf/2608.26208v1>
- Pretraining corpus size: 4,254,069 spatial cells across 10 samples, 4 tumor contexts, 2 imaging platforms [Paper: PDF p. 6]
- Model parameters: 2.3B (2,296,747,232) [Paper: PDF p. 6]
- Key modalities used: Specimen-matched imaging-based spatial transcriptomics (IST) + scRNA-seq, integrated via SpaIM [Paper: PDF p. 2, 7]
- Gene vocabulary: Imputed to shared 20,000-gene space [Paper: PDF p. 2, 7]
- Core architecture: Hierarchical transformer with two prediction heads — additive single-layer graph transformer (head 1) and multi-layer graph transformer (head 2) [Paper: PDF p. 2, 5]
- Evaluation design: Held-out cancer types (breast, colorectal, melanoma) and platforms (Xenium, MERFISH) not present in pretraining [Paper: PDF p. 7]

02 一句话总结

GITIII-scale 是首个可解释的、泛癌预训练的空间转录组基础模型，通过将 sender-receiver 细胞对、距离与直接接触建模为 token，并采用可分解的加性图归纳偏置 transformer（head 1）与高阶图 transformer（head 2），在 specimen-matched scRNA-seq + IST 数据上自监督学习细胞状态–微环境关联（cell state–niche correlation），其生成的 TME embedding 在未见癌症类型上优于现有空间基础模型，且能单细胞级归因 LR 通路（如 KDR 轴驱动内皮 MKI67 表达）[Paper: PDF p. 1–2, 9–10].

03 研究问题

- 如何从空间分辨的单细胞数据中，无偏地量化细胞状态偏离其细胞类型均值的程度（ z_i ）有多少可归因于其邻近微环境（ N_i ）？即建模 cell state–niche correlation [Paper: PDF p. 1–2].
- 如何使该建模过程可解释：不仅识别哪些细胞类型间存在相互作用，更需解耦每个 sender 细胞对 receiver 细胞每个基因的定量影响（influence tensor $I(g)_{ij}$ ）[Paper: PDF p. 2, 5].
- 如何使该建模具备泛化性：在未见过的癌症类型、平台和样本上仍能准确恢复 niche-associated state changes，而非仅拟合单个 dataset [Paper: PDF p. 2, 7].
- 如何将可解释的 influence tensor 桥接到已知生物学机制（如 ligand–receptor 通路），支持靶点发现 [Paper: PDF p. 2, 6].

04 研究背景与发展路径

-

临床动机：肿瘤微环境（TME）中细胞状态受邻近细胞调控；识别失调的细胞间互作（CCI）是药物靶点发现核心 [Paper: PDF p. 1-2].

- 技术缺口：scRNA-seq 提供全转录组但丢失空间；IST 提供单细胞空间但仅测 panel（312-6,175 genes）；二者单独均无法同时捕获 niche 与 induced state [Paper: PDF p. 2].

- 方法学缺口：

- 现有空间基础模型（TERRA, HEIST, Novae, SpatialFormer）目标为组织结构、空间域或细胞身份，不建模 cell state-niche correlation；其嵌入无法分解为 directional CCI 或下游转录效应 [Paper: PDF p. 2, 8, 15-16].

- 现有 CCI 工具（CellPhoneDB, NicheNet, NCEM）多为 dataset-specific，或依赖先验网络（覆盖有限），或无法 scale 到 pan-cancer、full-transcriptome [Paper: PDF p. 2, 8, 17].

- 演进路径：GITIII-scale 继承 GITIII（Xiao et al., 2025）的可解释性动机，但通过三方面升级实现 foundation model 能力：（1）双层架构分离可分解性（head 1）与表达力（head 2）；（2）pan-cancer 预训练（vs. per-dataset）；（3）基于 specimen-matched IST+scRNA-seq 的 20k-gene imputation [Paper: PDF p. 17-18].

05 论文识别的核心痛点

Pain point / Manifestation / Cause or author explanation / Evidence from the paper

Pain point: Lack of interpretable cell state-niche correlation modeling

Manifestation: Existing spatial foundation models cannot decompose predicted cell state into gene-level contributions from individual neighboring cells; they encode tissue architecture or domain identity, not how niche shifts state [Paper: PDF p. 2]

Cause or author explanation: Their objectives target spatial domains/cell identity/expression similarity — all orthogonal to quantifying how much a cell's deviation from its type mean is attributable to neighbors [Paper: PDF p. 2]

Evidence from the paper: "A model can therefore be perfectly domain-discriminative while carrying no information about how the niche shifted the receiver's state" [Paper: PDF p. 2]; Figure 1b highlights GITIII-scale's additive influence tensor as core interpretability mechanism [Paper: PDF p. 4].

Pain point: Inadequate data for full-transcriptome, single-cell spatial modeling

Manifestation: Models trained on spot-level data blur cell-level correlations; models trained on IST panel data only see a "panel-sized slice of the biology", missing ligands/receptors outside panel [Paper: PDF p. 2]

Cause or author explanation: Neither scRNA-seq (no space) nor IST (no full transcriptome) alone suffices; paired specimen data is rare but essential to impute full transcriptome at single-cell resolution [Paper: PDF p. 2, 7]

Evidence from the paper: Pretraining corpus uses specimen-matched IST+scRNA-seq integrated by SpaIM to impute to 20,000-gene vocabulary [Paper: PDF p. 2, 7, S23]; enables influence tensor over full transcriptome and LR attribution across platforms [Paper: PDF p. 17-18].

Pain point: Non-transferable CCI analysis

Manifestation: Previous deep learning CCI methods (e.g., Xiao et al., 2025; Li et al., 2023a) are dataset-specific and cannot generalize learned CCI features across samples/tissues [Paper: PDF p. 2]

Cause or author explanation: They lack large-scale pretraining on diverse biological corpora, so nothing learned in one tissue transfers to the next [Paper: PDF p. 17]

Evidence from the paper: GITIII-scale pretrained on 4.25M cells across 4 tumor contexts/2 platforms; ablation shows dataset-specific training fails to converge and underperforms

pan-cancer pretraining [Paper: PDF p. 9, S24].

Pain point: Unverifiable LR attribution

Manifestation: No ground truth exists for which LR pathway drives a given gene's expression change in a receiver cell type; current methods infer correlation, not causality [Paper: PDF p. 10]

Cause or author explanation: Biological validation is required but not yet performed; attribution relies on statistical association between received signal strength ($S(\ell, r)_i$) and measured cell-state $z(g)_i$ [Paper: PDF p. 10]

Evidence from the paper: Authors explicitly state limitation: "It is hard to systematically evaluate the analysis accuracy... our analysis can only tell correlation instead of causality" [Paper: PDF p. 10]; case study reports PCC=0.23, not causal inference [Paper: PDF p. 10].

06 核心思想

- Cell state–niche correlation as learnable mapping: Define $z_i = x_i - \mu_t(i)$ as cell state (deviation from cell-type mean), and model z_i as a function of N_i (neighborhood) — this isolates niche-induced variation from intrinsic cell-type programs [Paper: PDF p. 3, Eq. 1].
- Interpretability via strict additivity: Head 1 uses a single-layer graph transformer without feed-forward network, where per-gene attention scores $\alpha(g)_{ij}$ are normalized across senders (not genes), and prediction $\hat{z}(1)(g)_i = \sum_j I(g)_{ij}$ is an exact sum of sender-wise influences — no non-linear distortion preserves decomposability [Paper: PDF p. 5, Eq. 6].
- Hierarchical representation: Head 1 yields gene-level, sender-decomposed influence tensor $I \in \mathbb{R}^{N \times k \times G}$; Head 2 consumes same tokens to generate permutation-invariant TME embedding $h_i \in \mathbb{R}^{1024}$ capturing higher-order, combinatorial niche effects (e.g., co-presence requirements) [Paper: PDF p. 2, 5, Eq. 7].
- Bridging to biology via data-driven distance scaling: For each (receiver type, target gene) pair, fit a monotone spline $sc_{g,d}(d)$ to model how influence decays with distance — this is learned from data, not assumed globally, enabling accurate LR signal strength estimation $S(\ell, r)_i$ [Paper: PDF p. 6, Fig. 3b].

07 方法总览

GITIII-scale 是一个两阶段、自监督的 hierarchical transformer 模型：

- Input construction: For each receiver cell i , build neighborhood N_i of $k=49$ nearest cells; mask expression of i and all same-type neighbors to $\mu_t(i)$ to prevent interpolation artifacts [Paper: PDF p. 3, 22].
- Tokenization: Sender/receiver cells $\rightarrow$ separate MLPs $\rightarrow T=32$ tokens $\times d=256$ dim; distance $d_{ij} \rightarrow$ 5-feature expansion $\rightarrow u_{ij} \in \mathbb{R}^d$; contact $c_{ij} \in \mathbb{R}^d$ [Paper: PDF p. 3–4, S18].
- Pair encoding: Process $[S_j; u_{ij}; c_{ij}] \rightarrow SAB \rightarrow \hat{S}_{ij}$; then $[\hat{S}_{ij}; R_i; u_{ij}; c_{ij}] \rightarrow SAB \rightarrow H_{ij}$; pool via MCAB $\rightarrow e_{ij} \in \mathbb{R}^{256}$ [Paper: PDF p. 4–5, Eqs. 3–5].
- Head 1 (Additive): Map $e_{ij} \rightarrow$ per-gene attention logits & values $\rightarrow \alpha(g)_{ij}, I(g)_{ij} \rightarrow \hat{z}(1)(g)_i = \sum_j I(g)_{ij}$ [Paper: PDF p. 5, Eq. 6].
- Head 2 (TME embedding): Pool sender tokens $W_{pe1}, \dots, W_{peik}$ with $R_i \rightarrow MCAB \rightarrow h_i \in \mathbb{R}^{1024} \rightarrow \hat{z}(2)_i = W_{out} h_i$ [Paper: PDF p. 5, Eq. 7].
- Objective: Maximize per-gene Pearson correlation $\rho(g) = \text{corr}_{i \in B}(\hat{z}(g)_i, z(g)_i)$ within cell type B ; loss $LB = \sum_g w(g)[1 - \rho(g)] + \lambda \|\hat{z}(g) - \hat{\hat{z}}(g)\|^2$ [Paper: PDF p. 5, Eq. 8].
- LR attribution: From $I(g)_{ij}$, fit distance scaler $sc_{g,d}(d)$, weight receivers by

prediction fidelity ω_i , compute $S(\ell, r)_i = [\sum_j \text{sc}_{g, \ell}(d_{ij}) \cdot \text{gm}(x(\ell)_j)] \cdot \text{gm}(x(r)_i)$, regress $z(g)_{\ell}^i$ on all $S(\ell, r)_i$ via weighted LASSO [Paper: PDF p. 6, Eq. 9–10].

08 核心模块拆解

Module / Function / Why needed / Input and output / Supporting evidence / Known or expected effect of removal

Module: Same-type masking

Function: Replace expression of receiver cell i and all same-type neighbors in N_i with cell-type mean $\mu_t(i)$

Why needed: Prevents model from scoring well by interpolating between spatially autocorrelated same-type neighbors, forcing it to learn true CCI rather than local copying [Paper: PDF p. 3, 22]

Input and output: Input: raw expression x_i, x_j ; Output: masked expression = $\mu_t(i)$ for i and same-type j [Paper: PDF p. 3]

Supporting evidence: Described as critical for “fair comparison” and “truly evaluate whether models can encode cell state–niche correlations” [Paper: PDF p. 7]; ablation not shown but rationale is foundational [Paper: PDF p. 3, 22]

Known or expected effect of removal: Model would achieve high accuracy by copying neighbors, learning nothing about intercellular communication [Paper: PDF p. 3].

Module: Distance featurization ($\mathbb{X}(d)$)

Function: Expand scalar distance d_{ij} into 5 features spanning contact-range to diffusive scales (algebraic decay, cubic contact indicator, exponential decays at $0.76\mu\text{m}$ & $190.67\mu\text{m}$) [Paper: PDF p. 18, S5]

Why needed: Captures biophysically plausible signaling decay regimes; avoids assuming a single parametric form [Paper: PDF p. 18]

Input and output: Input: $d_{ij} (\mu\text{m})$; Output: $\mathbb{X}(d_{ij}) \in \mathbb{R}^5 \rightarrow$ embedded to $u_{ij} \in \mathbb{R}^2 \times \mathbb{R}^2$ [Paper: PDF p. 4, S18]

Supporting evidence: Distance scaler in Fig. 3b fits sharp decay within $\sim 20\text{--}50\mu\text{m}$, aligning with physical law [Paper: PDF p. 10]; ablation shows removing distance embedding causes 27% relative loss in variance explained [Paper: PDF p. 9]

Known or expected effect of removal: Performance drop of 0.0448 ($0.1684 \rightarrow 0.1236$) in variance explained on breast sample, confirming spatial info is crucial [Paper: PDF p. 9].

Module: Direct contact token (c_{ij})

Function: Binary token indicating if sender j and receiver i share edge in Delaunay triangulation, embedded to $c_{ij} \in \mathbb{R}^2 \times \mathbb{R}^2$

Why needed: Encodes juxtacrine signaling distinct from paracrine/diffusive; Delaunay identifies direct physical contact [Paper: PDF p. 3, 4]

Input and output: Input: binary contact flag; Output: $c_{ij} \in \mathbb{R}^2 \times \mathbb{R}^2$ [Paper: PDF p. 4]

Supporting evidence: Ablation shows removing contact embedding causes 0.0155 drop ($0.1684 \rightarrow 0.1529$) in variance explained [Paper: PDF p. 9]

Known or expected effect of removal: 9% relative loss in variance explained, second most damaging ablation after shrinking neighborhood [Paper: PDF p. 9].

Module: Single-layer graph transformer (Head 1)

Function: Compute per-gene attention $\alpha(g)_{ij}$ normalized across senders j , then $l(g)_{ij} = \alpha(g)_{ij} \cdot \text{WV}(e_{ij})(g)$, $\mathbb{X}z(1)(g)_i = \sum_j l(g)_{ij}$ [Paper: PDF p. 5, Eq. 6]

Why needed: Ensures exact additivity and decomposability: each $l(g)_{ij}$ is a clean, one-layer mapping from (i, j, d) features to influence on gene g , without GNN distortion [Paper: PDF p. 5]

Input and output: Input: $e_{ij} \in \mathbb{R}^2 \times \mathbb{R}^2$; Output: $l \in \mathbb{R}^{N \times k \times G}$, $\mathbb{X}z(1)_i \in \mathbb{R}^G$ [Paper: PDF p. 5]

Supporting evidence: Explicitly stated as “where the interpretability of the model is established” [Paper: PDF p. 5]; case study (Fig. 3) uses this head’s output [Paper: PDF p. 10]

Known or expected effect of removal: Loss of exact decomposability; influence tensor l would no longer directly represent sender-wise contributions, breaking interpretability pipeline [Paper: PDF p. 5].

Module: Multi-head cross-attention pooling (MCAB)

Function: Use $L=4$ learned latent queries to attend to token sets (H_{ij} or $[W_{pei1}, \dots, W_{peiL}; R_i]$) and return fixed-size, permutation-invariant summary [Paper: PDF p. 4–5]

Why needed: Enables handling variable neighborhood size ($k=49$) and ensures permutation invariance — critical for biological plausibility as sender order is arbitrary [Paper: PDF p. 4–5]

Input and output: Input: $H_{ij} \in \mathbb{R}^{(2T+4) \times d}$ or token list; Output: $MCAB(H_{ij}) \in \mathbb{R}^L \times d \rightarrow$ flattened $e_{ij} \in \mathbb{R}^{2 \times 24}$ or $h_i \in \mathbb{R}^{1 \times 24}$ [Paper: PDF p. 4–5, Eqs. 4–5, 7]

Supporting evidence: Described as producing “fixed-size, permutation-invariant summary” [Paper: PDF p. 4]; essential for both head 1 and head 2 [Paper: PDF p. 4–5]

Known or expected effect of removal: Model would not be invariant to sender ordering, violating biological expectation; output dimension would scale with k , breaking fixed embedding size [Paper: PDF p. 4].

09 关键公式与符号

ID / Formula / Meaning / Key symbols / Source

ID: Eq. 1

Formula: $x_i = \mu_t(i) + z_i, z_i = x_i - \mu_t(i)$

Meaning: Decomposition of cell expression x_i into cell-type mean $\mu_t(i)$ and cell state z_i (deviation)

Key symbols: x_i : measured profile; $\mu_t(i)$: mean of cell type $t(i)$; z_i : cell state component

Source: [Paper: PDF p. 3]

ID: Eq. 2

Formula: $S_j = \text{reshape}(\text{MLP}_{\text{snd}}(x_j)), R_i = \text{reshape}(\text{MLP}_{\text{rec}}(x_i)) \in \mathbb{R}^{T \times d}, T=32, d=256$

Meaning: Tokenization: sender/receiver cells mapped to $T=32$ tokens of width $d=256$

Key symbols: S_j : sender j tokens; R_i : receiver i tokens; $\text{MLP}_{\text{snd}}/\text{MLP}_{\text{rec}}$: separate encoders

Source: [Paper: PDF p. 4]

ID: Eq. 3

Formula: $\tilde{S}_{ij} = \text{SAB}([S_j; u_{ij}; c_{ij}]) \in \mathbb{R}^{(T+2) \times d}$

Meaning: Self-attention block on sender + distance + contact tokens

Key symbols: u_{ij} : distance token; c_{ij} : contact token; SAB : self-attention block

Source: [Paper: PDF p. 5]

ID: Eq. 4

Formula: $H_{ij} = \text{SAB}([\tilde{S}_{ij}; R_i; u_{ij}; c_{ij}]) \in \mathbb{R}^{(2T+4) \times d}$

Meaning: Self-attention block on combined sender-receiver interaction tokens

Key symbols: H_{ij} : interaction token set for pair (i, j)

Source: [Paper: PDF p. 5]

ID: Eq. 5

Formula: $e_{ij} = W_c \text{flatten}(MCAB(H_{ij})), MCAB(\cdot) \in \mathbb{R}^L \times d, e_{ij} \in \mathbb{R}^{256}$

Meaning: Cross-attention pooling to fixed-size vector per sender-receiver pair

Key symbols: $MCAB$: multi-head cross-attention block; $L=4$; W_c : linear projection

Source: [Paper: PDF p. 5]

ID: Eq. 6

Formula: $\alpha(g)_{ij} = \exp(W_A(e_{ij})(g)) / \sum_j' \exp(W_A(e_{ij}')(g)), l(g)_{ij} = \alpha(g)_{ij} W_V(e_{ij})(g),$

$\tilde{z}(1)(g)_i = \sum_j l(g)_{ij}$

Meaning: Additive head: per-gene attention, influence tensor, and prediction

Key symbols: W_A/W_V : MLPs; $\alpha(g)_{ij}$: attention score for gene g ; $l(g)_{ij}$: influence of j on i 's gene g

Source: [Paper: PDF p. 5]

ID: Eq. 7

Formula: $h_i = \text{flatten}(MCAB(\text{SAB}([W_{pei1}, \dots, W_{peiL}; R_i]))), \tilde{z}(2)_i = W_{\text{out}} h_i$

Meaning: TME embedding head: neighborhood pooling to $h_i \in \mathbb{R}^{1024}$

Key symbols: h_i : TME embedding; W_{out} : linear predictor; SAB : self-attention blocks

10 实验设计与证据链

Experiment / Claim tested / Comparison and conditions / Result / Supported conclusion / Unsupported stronger conclusion / Source

Experiment: Benchmarking on held-out samples

Claim tested: GITIII-scale recovers cell state–niche correlation better than existing foundation models on unseen cancer types/platforms

Comparison and conditions: Compared against TERRA, HEIST, Novae, SpatialFormer (frozen), NCEM-GCN, GAT, k-NN proportion probe; all use identical masked neighborhoods, downstream MLP probe (1024-unit hidden layer), train/val/test split (0.7/0.15/0.15), and 5 seeds [Paper: PDF p. 7–8, S15–S16]

Result: On Xenium Breast: GITIII-scale $R^2=0.168\pm0.003$, $PCC=0.398\pm0.004$; best baseline (TERRA) $R^2=0.146\pm0.001$, $PCC=0.370\pm0.002$ [Paper: PDF p. 15, Table S1]

Supported conclusion: GITIII-scale's TME embeddings encode cell state–niche correlation more effectively than those of other spatial foundation models in out-of-distribution settings [Paper: PDF p. 8]

Unsupported stronger conclusion: That GITIII-scale is universally superior across all tasks or datasets — baselines vary in strength by sample (e.g., TERRA best on melanoma) [Paper: PDF p. 8]

Source: [Paper: PDF p. 8, 15]

Experiment: Ablation: corpus size

Claim tested: Performance improves with larger, more diverse pretraining corpus

Comparison and conditions: Trained variants on cumulative subsets: 2.35M $\rightarrow$ 3.04M $\rightarrow$ 4.25M cells; same architecture, matched optimization steps [Paper: PDF p. 9, Fig. 2]

Result: Variance explained increases from 0.1290 at 2.35M to 0.1684 at 4.25M [Paper: PDF p. 9, Fig. 2]

Supported conclusion: Gains are attributable to corpus size/diversity, not extra optimization; scaling benefits hold [Paper: PDF p. 9]

Unsupported stronger conclusion: That performance would continue scaling linearly beyond 4.25M — no extrapolation tested

Source: [Paper: PDF p. 9]

Experiment: Ablation: model capacity

Claim tested: Model performance scales with parameter count

Comparison and conditions: Halved (0.9B) and quartered (0.4B) model width; same architecture otherwise [Paper: PDF p. 9, Fig. 2]

Result: Variance explained drops from 0.1684 (2B) to 0.1577 (0.9B) and 0.1489 (0.4B) [Paper: PDF p. 9, Fig. 2]

Supported conclusion: GITIII-scale's capacity is underutilized at 2B params; larger models may yield further gains [Paper: PDF p. 9]

Unsupported stronger conclusion: That 2B is the optimal size — no upper bound explored

Source: [Paper: PDF p. 9]

Experiment: Ablation: neighborhood size (k)

Claim tested: Signal extends beyond immediate neighbors

Comparison and conditions: Tested k=49 (original), k=35, k=25, k=10 on breast sample [Paper: PDF p. 9, Fig. 2]

Result: k=10 gives $R^2=0.1022$, a 39% relative loss vs. k=49 (0.1684) [Paper: PDF p. 9, Fig. 2]

Supported conclusion: Cell state–niche correlation involves broader cellular neighborhoods, not just adjacent cells [Paper: PDF p. 9]

Unsupported stronger conclusion: That k=49 is biologically optimal — no biological validation of k choice

Source: [Paper: PDF p. 9]

Experiment: Case study: endothelial MKI67

Claim tested: GITIII-scale identifies canonical, targetable LR pathways in unseen tissue

Comparison and conditions: Applied LR attribution pipeline (Sec 2.4) to predict MKI67 in endothelial cells of held-out breast sample [Paper: PDF p. 9–10]

Result: KDR (VEGFR2) axis selected top-ranked; received signal strength correlates with MKI67 (PCC=0.23, $P=3.3e-83$, $n=7064$); distance scaler fits sharp decay ~20–50 μ m [Paper: PDF p. 10, Fig. 3]

Supported conclusion: GITIII-scale can recover known pathogenic mechanisms (VEGF-KDR angiogenesis) in tissues absent from training, supporting its biological relevance and interpretability [Paper: PDF p. 10]

Unsupported stronger conclusion: That KDR inhibition would therapeutically suppress MKI67 — correlation $\neq$ causation; requires wet-lab validation [Paper: PDF p. 10]

Source: [Paper: PDF p. 10]

11 对结论的正确理解

- GITIII-scale 的优势在于 cell state–niche correlation recovery, not general spatial domain segmentation or cell typing — its objective (per-gene PCC on z_i) and evaluation (masked neighborhoods) are specifically designed for this [Paper: PDF p. 2, 5, 7–8].
- Its interpretability is architecturally enforced additivity, not post-hoc attribution (e.g., SHAP): the influence tensor $I(g)_{ij}$ is a direct, one-layer output of the model, not derived from gradients or perturbations [Paper: PDF p. 5, Eq. 6].
- The “pan-cancer” claim rests on training across 4 tumor contexts (liver HCC/iCCA, colon, liver HCC, ovarian) and 2 platforms (CosMx, Xenium), but does not include breast, colorectal, or melanoma in pretraining — these are held out for OOD evaluation [Paper: PDF p. 6, 7, S23].
- LR attribution (e.g., KDR) is a statistical correlation analysis applied post hoc to the influence tensor using external LR databases and distance modeling; it is not part of the model’s forward pass or training objective [Paper: PDF p. 6, 10].
- The 2.3B parameter count reflects the full dual-head architecture, but the key interpretability guarantee comes solely from Head 1’s constrained design (single-layer, no FFN, per-gene sender-normalized attention), which costs only ~2% PCC vs. Head 2 [Paper: PDF p. 9].

12 作者明确承认的限制

Limitation / Specific manifestation / Future direction proposed by authors / Source

Limitation: Data scarcity

Specific manifestation: Specimen-level matched scRNA-seq and IST data are rare, limiting corpus scale

Future direction proposed by authors: “We will keep collecting data to further scale the model” [Paper: PDF p. 10]

Source: [Paper: PDF p. 10]

Limitation: Causal inference gap

Specific manifestation: LR attribution identifies correlation, not causality; no ground truth for validation

Future direction proposed by authors: “Further biological validation will be performed to better evaluate and train our model” [Paper: PDF p. 10]

Source: [Paper: PDF p. 10]

Limitation: Input dependency

Specific manifestation: Requires imputed full-transcriptome data from specimen-matched IST+scRNA-seq, limiting applicability to datasets without such pairing

Future direction proposed by authors: Not explicitly stated, but implied by “it is important to note... our model requires inputs imputed from specimen-level paired IST and scRNA-seq data”

[Paper: PDF p. 11]

Source: [Paper: PDF p. 11]

Limitation: Baseline objective mismatch

Specific manifestation: Compared foundation models were not designed for cell state–niche correlation, so their underperformance reflects objective misalignment, not inherent inferiority

Future direction proposed by authors: Authors note “the comparison only reflects differences in model objectives and design” and that baselines “may underperform... in encoding cell state–niche correlations” [Paper: PDF p. 11]

Source: [Paper: PDF p. 11]

13 批判性分析

[Analysis] Observation / Potential issue or alternative explanation / Why it matters / How to test it / Basis

[Analysis] Observation: Distance scaler is fitted per (receiver type, target gene) pair, but LR attribution uses the same scaler for all LR pairs targeting that pair

Potential issue or alternative explanation: A single distance decay trend may not apply equally to all ligands acting on the same receptor/gene (e.g., VEGFA vs. PGF binding KDR may have different diffusion kinetics) [Paper: PDF p. 6]

Why it matters: Over-simplifies biophysical diversity of ligands; could misattribute signal if ligands have distinct ranges

How to test it: Fit separate scalers per LR pair (ℓ, r) instead of per (c, g); compare attribution stability and biological plausibility (e.g., does VEGFA get higher weight than PGF for KDR-MKI67?)

Basis: Authors state scaler is “estimated separately for each (receiver type, target gene) combination” but do not specify per-LR refinement [Paper: PDF p. 6].

[Analysis] Observation: Same-type masking removes all same-type neighbors, including potential autocrine/juxtacrine signals within a cell type

Potential issue or alternative explanation: Autocrine signaling (e.g., cancer cells secreting TGF β that acts on themselves) is biologically important but eliminated by masking [Paper: PDF p. 3, 22]

Why it matters: May blind the model to key intra-type regulatory loops, especially in homogeneous tumors

How to test it: Compare performance with partial masking (e.g., mask only other same-type neighbors, keep self) on datasets with known autocrine drivers (e.g., PDGF-PDGFR in glioblastoma)

Basis: Masking rule is absolute: “for cells within N_i that share the receiver’s type, including the receiver itself, their expressions are masked” [Paper: PDF p. 3].

[Analysis] Observation: LR attribution uses geometric mean (gm) for multimeric ligands/receptors, but assumes all subunits must be co-expressed in the same cell

Potential issue or alternative explanation: Many functional ligands/receptors (e.g., TNF α trimer, EGFR dimer) can form heteromultimers or be secreted/trans-presented; requiring all subunits in one cell is overly restrictive [Paper: PDF p. 6]

Why it matters: Could miss biologically real interactions where subunits are expressed in different cells (e.g., trans-presentation of MHC-II)

How to test it: Test alternative aggregation (e.g., max, sum) for gm in Eq. 10; assess impact on top-ranked axes and known biology (e.g., does it recover CD40-CD40L if CD40L is on T cells and CD40 on B cells?)

Basis: Authors define gm as “geometric mean over the subunits of a multimeric ligand or receptor” and state “a complex scores highly only when all of its components are present” [Paper: PDF p. 6].

[Analysis] Observation: The “additivity cost” comparison (Head 1 vs. Head 2 PCC) uses the same checkpoint, but Head 1’s output is not the final prediction used in benchmarking

Potential issue or alternative explanation: Benchmarking uses Head 2’s TME embedding h_i for the downstream probe [Paper: PDF p. 7], so the 2% PCC gap is between two internal heads, not between interpretable and final outputs

Why it matters: Overstates the “cost” of interpretability; the deployed model’s accuracy is Head 2’s, and Head 1’s role is purely for attribution

How to test it: Report the PCC of the final benchmarking prediction ($\text{MLP}(h_i) + \text{cell-type embedding}$) vs. a hypothetical probe using Head 1’s output — but Head 1 has no TME embedding, so this is architecturally impossible

Basis: Authors state “the two prediction heads also let us quantify the cost of interpretability directly” and report Head 1 PCC=0.1902 vs. Head 2=0.1934 [Paper: PDF p. 9].

14 学到的知识

- Cell state–niche correlation is a well-defined, quantifiable quantity: $z_i = x_i - \mu_t(i)$, and its correlation with neighborhood features is a valid self-supervised objective [Paper: PDF p. 1–3].
- Architectural constraints enable interpretability: A single-layer graph transformer with per-gene sender-normalized attention (Eq. 6) guarantees exact additivity — a powerful alternative to post-hoc methods [Paper: PDF p. 5].
- Distance featurization matters: Using multiple decay regimes (algebraic, cubic, exponential) in $\Box(d)$ [Paper: PDF p. 18] allows the model to learn biologically plausible interaction ranges (e.g., Fig. 3b’s ~20–50 μm decay) without assuming a parametric form.
- Specimen-matched multimodal integration is transformative: Pairing IST and scRNA-seq from the same specimen enables full-transcriptome imputation at single-cell resolution, unlocking pan-cancer learning and cross-platform LR attribution — a key enabler missing in prior work [Paper: PDF p. 2, 7, 17–18].
- Interpretability and performance need not trade off: The additive head loses only ~2% PCC vs. the deeper head [Paper: PDF p. 9], proving that strict decomposability can be achieved with minimal accuracy penalty.

15 与既有知识的连接

- single-cell foundation models: Contrasts with scGPT-spatial [Wang et al., 2025], which tokenizes genes and masks gene tokens; GITIII-scale tokenizes cells, making it inherently suited for CCI modeling [Paper: PDF p. 3, 15–16].
- spatial transcriptomics: Builds on TERRA/HEIST/Novae but shifts objective from spatial context to cell state–niche correlation; differs from SpatialFormer’s convolutional-transformer hybrid by using pure transformer blocks on cell tokens [Paper: PDF p. 2, 8, 15–16].
- graph neural networks: Uses graph transformers (not GCN/GAT) for neighborhood modeling; unlike NCEM-GCN [Fischer et al., 2022], it is pretrained, pan-cancer, and produces an interpretable influence tensor [Paper: PDF p. 2, 8, 17].
- multi-omics: Leverages specimen-matched scRNA-seq + IST as a data integration strategy, not a multi-modal fusion task — the scRNA-seq serves solely to impute the IST panel to 20k genes [Paper: PDF p. 2, 7, 17–18].
- biomedical AI: Embodies the “foundation model for target discovery” paradigm: pretrain on broad biological data, then apply frozen to specific disease contexts (e.g., breast cancer endothelial proliferation) for mechanistic insight [Paper: PDF p. 1–2, 9–10].
- perturbation prediction: While not predicting perturbations directly, the

influence tensor $I(g)_{ij}$ provides a quantitative basis for in silico perturbation:

e.g., ablating sender j would reduce $\sum_i z(g)_i$ by $I(g)_{ij}$ [Paper: PDF p. 5].

- cell state representation: Defines cell state z_i as deviation from cell-type mean, a standard approach in methods like NicheNet [Browaeys et al., 2019], but learns the mapping to niche end-to-end rather than propagating through a static prior network.

- cross-modal alignment: Alignment is achieved via specimen matching and imputation (SpaIM), not joint embedding or contrastive learning — a pragmatic, data-centric alignment strategy.

16 研究想法

- name: Specimen-free cross-platform LR attribution

originating limitation/observation: LR attribution requires specimen-matched IST+scRNA-seq for imputation, limiting applicability [Paper: PDF p. 11]; current imputation (SpaIM) is computationally heavy (5 days) [Paper: PDF p. 23].

core hypothesis: A foundation model can learn platform-invariant LR signaling representations directly from raw IST panels and public scRNA-seq atlases, bypassing specimen matching.

delta from paper: Replace specimen-matched imputation with contrastive alignment of IST panel embeddings (from GITIII-scale encoder) and scRNA-seq gene embeddings (from scGPT), using public atlases (e.g., Human Cell Atlas) as bridge.

initial method: Train GITIII-scale variant with dual-head: Head 1 (additive) on IST panels only; Head 2 (TME) contrastively aligned to scRNA-seq cell-type embeddings via InfoNCE loss on matched cell types.

validation: Test LR attribution on held-out IST samples without matched scRNA-seq; compare top axes to those from specimen-matched version (e.g., KDR in breast).

failure modes: Poor alignment if IST panel genes are sparse in scRNA-seq atlas; batch effects dominate contrastive signal.

innovation status: unverified

- name: Autocrine-aware neighborhood masking

originating limitation/observation: Same-type masking eliminates autocrine signals by design [Paper: PDF p. 3, 22], potentially missing key intra-tumor dynamics.

core hypothesis: A small fraction of same-type neighbors (e.g., the closest 1–3) carry biologically relevant autocrine/juxtacrine signals that should be preserved.

delta from paper: Modify masking to retain expression of the k_{closest} same-type neighbors (including self) while masking others, where k_{closest} is learned or set to 3.

initial method: Augment GITIII-scale's input construction: for receiver i , identify same-type neighbors in N_i , sort by distance, keep top- k_{closest} unmasked, mask the rest. Tune k_{closest} on validation PCC.

validation: Apply to tumor datasets with known autocrine drivers (e.g., EGFR ligands in lung adenocarcinoma); check if influence tensor shows strong self-influence on EGFR pathway genes.

failure modes: Increased risk of interpolation artifact if k_{closest} is too large; marginal gain if autocrine signals are weak relative to paracrine.

innovation status: unverified

- name: Multi-scale distance scalars per LR pair

originating limitation/observation: Distance scaler $sc_{g\boxtimes}(d)$ is fitted per (receiver type, target gene), not per LR pair, ignoring ligand-specific biophysics [Paper: PDF p. 6].

core hypothesis: Fitting scalars per $(\ell, r, c, g\boxtimes)$ triplet will improve LR attribution precision and biological plausibility.

delta from paper: Replace single scaler $sc_{g\boxtimes}(d)$ with $S(\ell, r, c, g\boxtimes)(d)$ in Eq. 10; use monotone splines per triplet, regularized by similarity to parent $(c, g\boxtimes)$ scaler.

initial method: For each $(\ell, r, c, g\boxtimes)$, fit spline to $l(g\boxtimes)_{ij}$ vs. d_{ij} for all j expressing ℓ and i expressing r ; penalize deviation from $sc_{g\boxtimes}(d)$ in loss.

validation: On breast case study, compare top-ranked axes with/without per-LR scalars; check if VEGFA-KDR gets higher weight than other KDR ligands (e.g., PGF) consistent with literature.

failure modes: Overfitting due to sparse data per triplet; increased computational cost for fitting thousands of splines.

innovation status: unverified

- name: Graph attention-guided influence tensor pruning

originating limitation/observation: Influence tensor $l(g)_{ij}$ is dense ($N \times k \times G$); many entries are near-zero but retained, bloating memory and obscuring key signals [Paper: PDF p. 5].

core hypothesis: A lightweight graph attention module can sparsify $l(g)_{ij}$ during inference, retaining only top-K sender-gene influences per receiver, guided by biological priors (e.g., LR database).

delta from paper: Add a pruning head that takes e_{ij} and LR database flags ($is_lr_pair(\ell, r)$) as input, outputs attention scores to select top-K (j, g) pairs for each i , zeroing others in l .

initial method: Train pruning head jointly with main model using Gumbel-Softmax for differentiable top-K selection; constrain $K=5$ per i .

validation: Measure sparsity (fraction of zeros in l) and correlation of pruned vs. full l with biological ground truth (e.g., known VEGF-responsive genes in endothelium).

failure modes: Pruning may remove weak but biologically critical signals; Gumbel-Softmax introduces noise.

innovation status: unverified

Weak connection/Methodology connection to user's research directions: All ideas connect to methodology (interpretable GNNs, cross-modal alignment, perturbation prediction) but lack direct ties to single-cell foundation models (GITIII-scale is spatial, not single-cell generic), spatial transcriptomics (covered), graph neural networks (core), multi-omics (specimen-matching is omics-integration), biomedical AI (core), perturbation prediction (influence tensor enables it), cell state representation (z_i definition), cross-modal alignment (SpaIM-based). No direct link to spatial transcriptomics beyond what's already central, and none to single-cell foundation models as typically defined (gene-token, not cell-token).
